ABSTRACT

Objective: This study aimed to investigate the potential role of microsatellite polymorphisms of the estrogen receptor alpha gene (ESR1) TA repeat, estrogen receptor beta gene (ESR2) CA repeat, and androgen receptor gene (AR) CAG and GGN repeats among Serbian women with primary ovarian insufficiency (POI). These microsatellites have been reported to be associated with POI in different racial/ethnic populations.

Methods: A cohort of 196 POI cases matched with 544 fertile controls was recruited by the Institute for Endocrinology, Diabetes and Metabolic Disorders of Serbia between 2007 and 2010. DNA was extracted from saliva. The four microsatellites were genotyped using a PCR-based assay to determine the repeat lengths.

Results: POI patients carried shorter repeat lengths of ESR2 (CA)\textsubscript{n} than controls (P = 0.034), but the difference was small. ESR1 (TA)\textsubscript{n} was on the borderline of statistical differences between groups (P = 0.059). AR (CAG)\textsubscript{n} and (GGN)\textsubscript{n} showed no association with POI.

Conclusions: We cautiously conclude that microsatellite polymorphisms of gonadal steroid receptor genes might contribute to the genetic basis of POI in Serbian women, but a larger-scale study and family-based studies are warranted to validate our findings even though the sample size in this study is larger than any previously published in this field.

Introduction

The average age for menopause in Western populations is approximately 51 years. Primary ovarian insufficiency (POI) (previously called premature ovarian failure) is characterized by amenorrhea, hypoestrogenism, and elevated gonadotropins, and affects 1% of women under the age of 40\textsuperscript{1,2}. The causes of POI are heterogeneous, including chromosome X defects, infections, iatrogenic effects (surgery, chemotherapy, radiation), and autoimmune diseases\textsuperscript{3}. Approximately 20–30% of women with POI will have other affected female family members\textsuperscript{4}, hence a genetic basis for the disorder is a likely cause for this clinical scenario. It is known that normal ovarian development and function require the expression and proper coordination of many genes\textsuperscript{5}. The underlying mechanisms are largely unknown and, despite the genetic defects identified in several candidate genes\textsuperscript{5–9}, in a large proportion of POI cases no cause has been found; hence they are classified as idiopathic POI.

Genotype-to-phenotype association mapping commonly utilizes two major classes of variants: single nucleotide polymorphisms and copy number variation. Microsatellites or short tandem repeats are informative genetic markers in the human genome and some might have biological functions depending upon their locations (coding regions or regulatory regions), so they are well established as a third major class of genotypic variation\textsuperscript{10}. Considering that the initial follicular pool size and the rate of follicular depletion are associated with the age of menopause and given the fact that these germ cells express gonadal steroid receptors at various stages of development, it is plausible that genetic variants in sex hormone receptor genes involved in maintaining ovarian function could affect the risk of POI\textsuperscript{11}. Ligand-bound gonadal steroid receptors act as DNA trans-activation factors and are thus responsible for mediating the effects of steroids on development, reproduction, proliferation, cellular homeostasis, and gene expression\textsuperscript{12,13}. Estrogen contributes to the regulation of cyclic gonadotropin release via its action on estrogen receptor alpha, encoded by ESR1, in the hypothalamic–hypophyseal axis and to enhancing folliculogenesis through its actions via estrogen receptor beta, encoded by ESR2, in the ovary\textsuperscript{14}. A dinucleotide TA tandem repeat polymorphism is located in the promoter region of ESR1, while a dinucleotide CA tandem repeat is located in intron 5 of ESR2. The functional significance of ESR1 (TA)\textsubscript{n} and ESR2 (CA)\textsubscript{n} in POI remains unknown, although previous
studies have shown associations between these two microsatellites and POI. The androgen receptor (AR), the only sex hormone receptor gene encoded on the X chromosome, is essential for the male reproductive process. AR expression in the development of follicles in rat ovary has been described, and excess androgen production causes infertility in polycystic ovary syndrome, so it is plausible that AR-mediated androgen signaling plays an important physiological role in the female reproductive system. Furthermore, AR-knockout mice have low follicle counts and eventually develop POI phenotypes. Within the first exon of the AR gene lie two microsatellite polymorphisms, one with a CAG repeat [(CAG)]n and one with a GGN repeat [(GGN)]n. A limited number of studies have found an association of CAG repeats of the AR gene in POI while others have not, and for the GGN repeats a significant association has been demonstrated with POI in Indian women.

Based on this evidence, we hypothesize that these key receptors of reproductive hormones might have roles in folliculogenesis and ovarian function; therefore, the present study was undertaken to investigate whether the ESR1 (TA)n, ESR2 (CA)m, AR (CAG)n, and AR (GGN)n repeat polymorphisms are associated with POI in Serbian women. This is the first study, with a larger cohort size than any previously published, to investigate these four microsatellites in gonadal steroid receptor genes in relation to POI in a well-defined ethnic group of patients and matched controls.

Methods

Patients and controls

The study population comprised native Serbian women of the same socioeconomic status and eating habits. The study population was selected from a larger group of young women with amenorrhea referred to the Institute for Endocrinology, Diabetes and Metabolic Disorders of Serbia, University of Belgrade. A cohort of 196 women diagnosed with idiopathic POI who fulfilled the inclusion criteria of the study was enrolled into the study. All patients completed a questionnaire on menstrual history, parity, family history of POI, education, and the experience of stresses prior to amenorrhea. The diagnosis was made in otherwise healthy women who fulfilled the criteria of amenorrhea of more than 12 months duration before the age of 40 years and both follicle stimulating hormone (FSH) >40 IU/L and estradiol <50 pmol/L. Women who had undergone gynecological operations (hysterectomy, ovarian cystectomy, or oophorectomy), those who had a history of drug abuse, and those with conditions known to cause ovarian failure such as metabolic disorders (e.g., galactosemia), autoimmune disorders, irradiation, or chemotherapy were excluded. In addition, all women diagnosed with POI included in this study had normal results for the following: full blood count, fasting glucose and lipoprotein profile, prolactin, testosterone, androstenedione, dehydroepiandrosterone (DHEA) sulfate, 17-OH progesterone, thyroxine, thyroid stimulating hormone, parathyroid hormone, and adrenocorticotropic hormone, and cortisol. All patients had low inhibin B and anti-Müllerian hormone levels. Normal results of a 2-h 75-g oral glucose tolerance test with glucose and insulin measured at 30-min intervals were part of the inclusion criteria. These patients also tested negative for antiovian, anticardiolipin, anti-thyroglobulin, and anti-microsomal antibodies. In this study, all women who developed POI under the age of 30 years had a normal karyotype. Pelvic ultrasound scan on all patients showed no ovarian pathology or follicular activity.

As controls, we recruited 544 healthy regularly menstruating women not using any hormonal treatment which could interfere with menstruation. All women included in the present study have signed a written consent form approved by the local ethics committee in Belgrade.

The mean age at diagnosis of POI was 34.2 ± 3.9 years in the patient group and the control group had a mean age of 36.0 ± 3.6 years with 46% parity.

Microsatellite genotyping

Genomic DNA was extracted from saliva using Oragene® OG-300 DNA sample collection kits (DNA Genotek Inc., Canada) following the manufacturer's protocol. Microsatellite markers were amplified by conventional polymerase chain reaction (PCR), using fluorescently labeled primers from Sigma, UK.

Genotyping for the ESR1 (TA)n, and ESR2 (CA)m polymorphisms was performed by PCR amplification in a total volume of 10 μl containing 10 ng DNA for ESR1 (TA)n or 2 ng DNA for ESR2 (CA)m after optimization, 0.25 mm each dNTP, 1.5 mM MgCl2, 0.5 U Taq DNA Polymerase (KAPA Biosystems, USA), and 0.4 μM of each of the primers. We designed forward primer 5′-6FAM-TTAGGCTGACGAAAAGAAGG-3′ and reverse primer 5′-TGTATTACATTGTGCGATTGTCG-3′ for the ESR1 (TA)n analysis, and forward primer 5′-HEX-GGCTGTACCCAGGTTGTG-3′ and reverse primer 5′-TCAGGC TGTCTCGAAGTCC-3′ for the ESR2 (CA)m analysis. The temperature profile was 95 °C for 5 min, followed by 30 cycles of 95 °C for 30 s, 62 °C for 30 s, and 72 °C for 20 s, and a final incubation at 72 °C for 2 min.

Genotyping for the AR (CAG)n, and (GGN)n polymorphisms was performed by PCR in a total volume of 10 μl containing 10 ng DNA for AR (CAG)n or 2 ng DNA for AR(GGN)n after optimization, 0.3 mM each dNTP, 2.0 mM MgCl2, 0.2 U High-Fidelity HotStart DNA Polymerase (KAPA Biosystems, USA), and 0.3 μM of each of the primers. We designed forward primer 5′-HEX-AGATTCAGGCAAGGCTCAGG-3′ and reverse primer 5′-CTCATCAGACAGGCTAGC-3′ for the CAG repeat analysis, and forward primer 5′-6FAM-CTTCTTA CGCCGAAGAAGG-3′ and reverse primer 5′-GGATA GGCGACTCTGCTC-3′ for the GGN repeats analysis. The temperature profile was 95 °C for 5 min, followed by 30 cycles of 98 °C for 20 s and 60 °C for 15 s, and a final incubation at 72 °C for 5 min.

For fragment-length determination, 1.0 μl of PCR product was mixed with 0.2 μl of MapMarker® 1000-ROX (BioVentures, Inc., USA) and 9.8 μl of Ultra-pure formamide (AGTC Bioproducts Ltd, UK). Upon denaturation for 5 min at 96 °C and cooling for 5 min on ice, samples were run on an ABI...
310x1 Genetic Analyzer (Applied Biosystems, USA) and the repeat lengths were subsequently checked and assigned in Genemapper® software (version 4.0; Applied Biosystems).

Quality control

One anonymous genomic DNA sample and a reaction without a DNA template were included in each set of PCR amplifications performed and run for every microsatellite length-determination experiment, as positive and negative controls, respectively. This ensured consistency of allele calling between PCR amplification batches. In addition, 10% of samples were randomly selected and the length determinations repeated to test the assay reproducibility. Furthermore, to confirm the precise repeat number, 16 PCR amplification products of different sizes as determined by Genemapper® analyses were subjected to direct sequencing on an Applied Biosystems 3730 sequencer (Applied Biosystems, USA). Repeat lengths measured by sequencing were successfully confirmed the precise repeat number, 16 PCR amplification repeated to test the assay reproducibility. Furthermore, to confirm the precise repeat number, 16 PCR amplification products of different sizes as determined by Genemapper® analyses were subjected to direct sequencing on an Applied Biosystems 3730 sequencer (Applied Biosystems, USA). Repeat lengths measured by sequencing were successfully assigned to corresponding peak positions determined by fluorescence-based length-determination genotyping.

Statistical analysis

The repeat lengths for ESR1 (TA)n, ESR2 (CA)n, AR (CAG)n, and AR (GGN)n were classified as both continuous and categorical variables, separately. For the continuous variable analysis, allele frequencies are summarized by the mean and standard deviation. As no hypothesis existed about which alleles would be associated with POI, a two-tailed Student’s t test was used to compare allele frequencies between POI patients and controls.

In addition, the genotype was also classified using the median repeat length in the control group as the cutoff value16,23, where microsatellite repeat alleles were coded as long repeats (denoted by L) and short repeats (denoted by S). As a result, three genotype classes can be defined for each of the four short tandem repeats: LL, LS, and SS. The cutoff limits were 17 (S ≤ 17; L ≥ 17) for ESR1 (TA)n, 23 (S < 23; L ≥ 23) for ESR2 (CA)n, 22 (S < 22; L ≥ 22) for AR (CAG)n, and 23 (S < 23; L ≥ 23) for AR (GGN)n. Comparisons of genotype distributions between the case and control groups were then performed using logistic regression models. Odds ratios were calculated by logistic regression analysis with 95% confidence intervals (CIs). All statistical results with P < 0.05 were considered statistically significant.

Results

The allele distributions of each individual microsatellite ESR1 (TA)n, ESR2 (CA)n, AR (CAG)n, and (GGN)n between the 196 POI cases and the 544 controls are similar (Figure 1).

ESR1

The TA repeat lengths in ESR1 ranged from 7 to 27 with a median length of 16 in POI patients and from 10 to 29 with a median length of 17 in controls. This polymorphism displayed a bimodal distribution, with peaks at 15 repeats and 24 repeats (Figure 1). The difference in the frequency distribution of the TA dinucleotide repeat polymorphism of the ESR1 gene between 196 POI cases (392 chromosomes) and 544 controls (1088 chromosomes) was not significant (P = 0.059) (Table 1). POI patients tended to have shorter repeat lengths, but no significant difference in the (TA)n repeat genotype distribution (SS, SL, and LL) was observed between the two groups (P = 0.121) (Table 2).

ESR2

The CA repeat lengths in ESR2 ranged from 10 to 28 with a median length of 22 in POI patients and from 15 to 29 with a median length of 23 in controls. The mean number of (CA)n repeats was lower in POI patients compared to the controls (P = 0.034), but this difference was small (Table 1). According to the categorical repeat length cutoff value of 23, comparisons of the ESR2 (CA)n genotypes (SS, SL, and LL) between POI case and control groups showed no significance (P = 0.075), although POI patients are more likely to have the SS genotype (27.6% vs. 21.5%), and individuals with SS and SL genotypes (enrichment of the S allele) are more common in the POI patient group (P = 0.045) (Table 2).

AR

The CAG repeats in AR ranged from 12 to 31 with a median length of 22 in POI patients and from 8 to 35 with a median length of 22 in controls. The difference of the distribution of CAG repeats was not significant between POI cases and controls (P = 0.071). The GGN repeats in AR ranged from 7 to 29 with a median length of 23 in both POI patients and controls, and there was no statistical difference observed between POI cases and controls (P = 0.620) (Table 1).

Discussion

The results of the present study demonstrate that microsatellite ESR2 (CA)n could play a potential role in the genetic mechanism for the etiology of POI, but ESR1 (TA)n, AR (CAG)n, and AR (GGN)n are not associated with POI in Serbian women.

The ESR1 gene has a very complex promoter organization. It contains multiple promoter regions with alternative splice sites, resulting in expression of alternative first exons and different protein isoforms25. It has been reported that the number of ESR1 (TA)n repeats differs by ethnicity, with estimated major peaks at 14 repeats in European populations and 15 repeats in Asian populations25. In the present study, the major peak of ESR1 (TA)n was at 15 repeats in our Serbian population, rather than 14 repeats in other European populations. We found that Serbian patients with POI had slightly shorter repeat lengths than controls, but the P value was at the borderline of significance. This finding is consistent with a study in Korean populations suggesting that ESR1 (TA)n does not contribute to the development of POI in women11. Furthermore, it has been reported that short alleles in ESR1 (TA)n were significantly less...
common in POI, and SS alleles were rare in patients with POI in a Caucasian with Asian admixture population\textsuperscript{16}, but we found that the SS genotype in Serbian patients with POI was more common than in controls (30.6% vs. 23.3%).

For \textit{ESR2} (CA)\textsubscript{n}, our analysis of continuous variables showed that more patients with POI had shorter repeat lengths. This means that the women who carry the S allele might have greater chance of developing POI. \textit{ESR2} (CA)\textsubscript{n} was first characterized as a highly polymorphic (CA) dinucleotide repeat in a Japanese population in 1998\textsuperscript{25}. Since then, the only published report investigating a possible link between \textit{ESR2} (CA)\textsubscript{n} and POI failed to establish any significant association\textsuperscript{16}. To the best of our knowledge, this is the first report demonstrating that the \textit{ESR2} (CA)\textsubscript{n} repeat polymorphism is statistically associated with POI. The POI patients in this study also tended to have shorter TA repeat lengths in \textit{ESR1} (although the association did quite reach statistical significance), hence S alleles in \textit{ESR1} and \textit{ESR2} might be considered as risk factors in POI in Serbian women.

We analyzed the coding-region tandem repeats of the \textit{AR} gene: an 8–35 CAG repeat (encoding polyglutamine, polyQ) and a 7–29 GGN repeat (encoding polyglycine, polyG). Together, these polymorphisms result in approximately 90% of women being heterozygous for alleles of the \textit{AR} gene. The polyglutamine and polyglycine tracts flank the activating function-1 domain of the AR protein and both have been reported to be modulators of AR transcription factor activity\textsuperscript{27}. The CAG polyglutamine stretch in the amino-terminal domain of the AR gene appears to inversely influence the function of the receptor as a transcription factor, and is assumed to be involved in interactions between the AR

ESR1, estrogen receptor alpha gene; ESR2, estrogen receptor beta gene; AR, androgen receptor gene; POI, primary ovarian insufficiency; OR, odds ratio; CI, confidence interval, L, long repeats; S, short repeats.

protein and different co-activators, with long repeats being inhibitory to these interactions which could explain the lower activity of the receptor. Our analysis of continuous variables showed that variants in AR (CAG)$_n$ and AR (GGN)$_n$ did not appear to be associated with POI in our patient cohort. Among the four microsatellites examined, AR (CAG)$_n$ is the most commonly tested in POI in the literature, and the conflicting reports concerning allele lengths can possibly be explained by genetic differences in diverse populations and perhaps by different sample sizes. Based on our results, we can only cautiously draw a conservative conclusion that the variants of AR (CAG)$_n$ and (GGN)$_n$ do not play a major role in follicle dysfunction in POI.

Classifying the repeats as SS, SL, and LL genotypes revealed that the majority of the cases and controls had the SL genotype more frequently than the SS and LL genotypes for ESR1 (TA)$_n$, ESR2 (CA)$_n$, and AR (CAG)$_n$. However, for the AR (GGN)$_n$ repeat, the LL genotype was most frequent. To gain an insight into clinical significance, the CIs in the categorical variable genotype analysis of these four microsatellites (Table 2) were calculated. However, most CIs are quite wide, so the true difference between patients with POI and the controls cannot be ruled out, and a much larger cohort would be required to overcome this limitation.

We conclude that patients with POI harbor shorter repeats in ESR2 (CA)$_n$ and S alleles in that gene might be considered a risk factor for POI in Serbian women. However, no convincing evidence was found in this study for an association between ESR1 (TA)$_n$, AR (CAG)$_n$, and (GGN)$_n$ repeat lengths and POI in Serbian women. We did assess whether the combined presence of microsatellite variants had an impact on the risk of POI, but could not identify any contribution by particular combinations of variants in each of the genes that were tested, with and without adjustment for age.

POI is now considered a multifactorial disease, where the phenotype is most probably the result of sequence variation in more than one gene. The current study is based on a clinically well-defined cohort with homogeneous racial background, and confirmation of these observations could be obtained by demonstration of co-inheritance of variants and POI in families. The effect of gonadal steroid receptor gene polymorphisms on the follicular pool size or rate of follicular depletion and the role of germline genetic variants in the etiology of POI remain to be further clarified and explored. The analysis of microsatellite length variability in this study, and of single nucleotide polymorphisms in other studies, can help in further understanding regulatory mechanisms that determine oocyte reserves and their depletion. Such data can be used in constructing variant-testing strategies that can help in screening women with menstrual irregularities suggestive of a transition to premature ovarian insufficiency.

Authors’ roles J.L. contributed to the study design, data analysis and manuscript preparation; R.D. contributed to the study design and edited the manuscript; S.V., S.D-D., M.I., M.I. and M.T. contributed to the clinical sample collection, biochemical analyses and assembly of data; J.T. contributed to statistical analysis of the data; F.A-A. contributed to the study design and participated in the critical discussion.

Conflict of interest No potential conflict of interest was reported by the authors.
Source of funding This study was supported by a grant from the Institute of Women’s Health Charity, Leicester, UK.
